RNA-guided genome surgery using CRISPR-Cas9 nucleases has shown promise for the treatment of diverse genetic diseases. Yet, the potential of such nucleases for therapeutic applications in nongenetic diseases is largely unexplored. Here, we focus on age-related macular degeneration (AMD), a leading cause of blindness in adults, which is associated with retinal overexpression of, rather than mutations in, the VEGFA gene. Subretinal injection of preassembled, VEGFA gene–specific Cas9 ribonucleoproteins (RNPs) into the adult mouse eye gave rise to mutagenesis at the target site in the retinal pigment epithelium. Furthermore, Cas9 RNPs effectively reduced the area of laser-induced choroidal neovascularization (CNV) in a mouse model of AMD. Genome-wide profiling of Cas9 off-target effects via Digenome-seq showed that off-target mutations were rarely induced in the human genome. Because Cas9 RNPs can function immediately after in vivo delivery and are rapidly degraded by endogenous proteases, their activities are unlikely to be hampered by antibody- and cell-mediated adaptive immune systems. Our results demonstrate that in vivo genome editing with Cas9 RNPs has the potential for the local treatment for nongenetic degenerative diseases, expanding the scope of RNA-guided genome surgery to a new dimension.

[Supplemental material is available for this article.]

Age-related macular degeneration (AMD) is the leading cause of blindness in aged populations in developed countries (Jager et al. 2008). Choroidal neovascularization (CNV) is a major pathologic feature of neovascular AMD and is caused primarily by angiogenic cytokines such as vascular endothelial growth factor A (VEGFA). In fact, VEGFA is a major therapeutic target for the treatment of AMD using monoclonal antibodies or aptamers since it emerged as an important factor in angiogenesis (Leung et al. 1989). Currently, intravitreous anti-VEGFA therapy is a mainstay of treatment for neovascular AMD (CATT Research Group et al. 2011; Schmidt-Erfurth et al. 2014). However, these anti-VEGFA agents must be injected at least seven times per year, because VEGF is continuously overexpressed in and secreted from diseased retinal pigment epithelium (RPE) cells. In this clinical circumstance, we reasoned that targeted inactivation of the VEGFA gene in RPE cells could reduce the VEGF level below a pathological threshold, leading to a long-term or permanent treatment of AMD, possibly in combination with current anti-VEGFA therapy.

The type II CRISPR-Cas9 systems, repurposed from prokaryotic adaptive immune responses, are now widely used for targeted genome modifications in plants, animals, and human cells (Kim et al. 2014; Woo et al. 2015; Zuris et al. 2015). In particular, Cas9 nucleases have shown promise for gene and cell therapy (Maeder and Gersbach 2016). Typically, these nucleases are expressed or delivered in vivo using plasmid DNA or viruses (Yin et al. 2014; Ran et al. 2015). However, plasmid DNA delivery is often inefficient, especially in vivo, and can cause integration of small plasmid fragments degraded by endogenous nucleases at on-target and off-target sites in the genome (Kim et al. 2014). Viral delivery of Cas9 can be highly efficient in vivo (Ran et al. 2015; Long et al. 2016; Nelson et al. 2016; Tabebordbar et al. 2016), but may be hampered by antibodies or T cells induced against the protein (Shankar et al. 2007; Calcedo et al. 2015; Chew et al. 2016). We and others have shown that preassembled Cas9 ribonucleoproteins (RNPs) can be delivered to human primary and stem cells and mice to modify target genes (Kim et al. 2014; Schumann et al. 2015; Zuris et al. 2015). Cas9 RNPs are rapidly turned over in cells, reducing off-target effects. Furthermore, Cas9 RNPs are unlikely to be limited by host immune systems because they function and disappear before the generation of antibodies and T cells directed against them. Currently, despite these advantages of RNPs, the difficult delivery of Cas9 RNPs in vivo limits its utility for therapeutic applications (Zuris et al. 2015). Here, we show that in vivo genome editing of an wild-type gene, whose up-regulation is responsible for pathogenesis, could be a new therapeutic modality for the treatment of nongenetic degenerative diseases. Our ultimate goal is to harness Cas9 RNPs for a clinical application of therapeutic genome surgery in patients with AMD.

Results

To investigate the potential of Cas9 RNP-mediated in vivo genome surgery for the treatment of AMD, we first identified Cas9 target
sites that are conserved in both the human VEGFA gene and the mouse Vegfa gene using Cas-Designer (Park et al. 2015a) and that differ from any other site in the human genome by at least two or three nucleotides using Cas-OFFinder (Bae et al. 2014). We tested four single-chain guide RNAs (sgRNAs) targeting these sites in exons 3 and 4 (labeled as Vegfa-1, 2, 3, and 4), which encode binding sites for VEGF receptors 1 and 2, respectively, in the mouse NIH3T3 cell line (Supplemental Table S1; Supplemental Fig. S1) and the human RPE cell line (ARPE-19). The most active VEGF-1 sgRNA complexed with the recombinant Cas9 protein and delivered via transfection using cationic lipid induced small insertions and deletions (indels) at the target site with a frequency of 82 ± 5% or 57 ± 3% in NIH3T3 cells or ARPE-19 cells, respectively (Fig. 1A–D). At day 2 post-treatment, Cas9 RNP delivery was much more efficient than plasmid transfection in these cells (Fig. 1C). We also carried out additional experiments using confluent ARPE-19 cells. Cells were harvested at 64 h after transfection and were analyzed using deep sequencing, qPCR, and ELISA to measure indel frequencies, mRNA levels, and protein levels, respectively. Indels were detected at a frequency of 40 ± 8% in the Vegfa-RNP-treated ARPE-19 cells (Fig. 1E). The Cas9 RNP reduced the VEGFA mRNA level by 24 ± 4% and the VEGFA protein level by 52 ± 9% in confluent ARPE-19 cells under post-mitotic conditions (Fig. 1F,G).

To monitor the localization of Cas9 RNPs in vitro and in vivo, we used Cy3-conjugated Cas9 protein (Deng et al. 2015). Thus, Cy3-Cas9 combined with or without the VEGF-1 sgRNA was mixed with cationic lipids and delivered into NIH3T3 cells. The Cy3-Cas9 RNP was detected in many nuclei (Fig. 2A,B) and induced indels at the target site (Fig. 2C,D). Interestingly, the proportion of Cy3-positive nuclei (42 ± 6%) (Fig. 2B) was almost equal to the frequency of indels (40 ± 3%) (Fig. 2D) at the target site, suggesting that target sites were almost completely cleaved in cells by nucleus-localized Cas9, and the rate-limiting factor in genome editing was nuclear localization of Cas9. Cy3-Cas9 alone was rarely detected in nuclei and did not induce indels (Fig. 2A,D). Note that Cas9 is a positively charged protein with a pl value of 9.12 and cannot form a complex with cationic lipids in the absence of negatively charged sgRNAs. The Cy3-Cas9 RNP, however, was less active than the unlabeled Cas9 RNP, which induced target-specific mutations at a frequency of 80%.

Next, we delivered the Vegfa-specific, Cy3-labeled or -unlabeled Cas9 RNP into the adult mouse eye via subretinal injection.
Cy3 dye was observed in the nuclei of the RPE in vivo 3 d after the injection (Fig. 2E). Notably, the subretinal injection of the Cy3-unlabeled Cas9 RNP gave rise to indels with a frequency of 25 ± 3% in RPE cells in the RNP-injected area at day 3 post-injection (\( n = 5 \)) (Fig. 2F; Supplemental Fig. S2A). Subretinal injection of RNPs did not induce detectable on-target indels in the neural retinal tissue or in the remnant RPE-choroid-sclera complex after RPE removal. Thus, in our experiments, subretinal injection of RNPs can induce indels in RPE cells in the injected area. We also performed Western blot analysis and found that the Cas9 protein was degraded completely at day 3 post-injection (Fig. 2G), showing that Cas9 was rapidly turned over in vivo. Considering that Cas9 expression in vivo using adeno-associated virus (AAV) can evoke host immune responses with distinct cellular and molecular signatures (Chew et al. 2016), rapid degradation of Cas9 after RNP delivery has an advantage for in vivo application.

Encouraged by the efficient delivery and high mutation frequency of the Vegfa-specific Cas9 RNP in vitro and in vivo, we investigated whether the Cas9 RNP could be used for the treatment of CNV in a mouse model of AMD (Lambert et al. 2013). Mice with laser-induced CNV were treated by subretinal injection of the Vegfa-specific Cas9 RNP or Rosa26-specific Cas9 RNP (Fig. 3A). The Rosa26-RNP was used as a negative control. At day 3 post-injection, indels were analyzed in RPE cells in the Cas9 RNP-injected CNV area. Cas9-induced indels were detected at a frequency of 22 ± 5% or 24 ± 2% in the Vegfa-RNP-treated or the Rosa26-RNP-treated CNV (\( n = 5 \)), respectively (Fig. 3E, F; Supplemental Fig. S2B), demonstrating that subretinal injection of the Vegfa-RNP can lead to local treatment in the eye. In addition, the Vegfa-RNP effectively reduced the concentration of the VEGFA protein in the CNV area (300 ± 20 pg/mL, \( n = 10 \), \( P < 0.001 \), One-way ANOVA and Tukey post-hoc tests) (Fig. 3D). At day 7 post-injection, a therapeutic effect was evaluated by assessing the CNV area. In mice treated with the Vegfa-RNP, the CNV area was significantly reduced (58 ± 4%, \( n = 15 \), \( P < 0.001 \), Student’s t-test), compared to that in Rosa26-RNP injected mice (Fig. 3B, C). Our results suggest that targeted inactivation of Vegfa in the RPE using Cas9 RNPs enables therapeutic genome surgery for the local treatment of AMD.
A critical issue in therapeutic genome surgery is the target specificity of CRISPR-Cas9 nucleases. We investigated whether the Vegfa-RNP used in this study caused any off-target mutations in the mouse eye or in human cells. First, using Cas-OFFinder (Bae et al. 2014), we identified 20 potential off-target sites in the mouse genome that are most highly homologous to the Cas9 target site (Supplemental Table S2). Genomic DNA was isolated from the Cas9 RNP-injected area or from the opposite noninjected area (RNP-free area) was analyzed by deep sequencing. VEGFA ELISA was performed at day 3 post-injection. Representative laser-induced CNV stained with isolectin B4 (IB4) in C57BL/6J mice injected with the Rosa26-specific Cas9 RNP (as a control) or the Vegfa-RNP. The yellow line demarcates the area of CNV. (C) The CNV area. Error bars indicate SEM (n = 15). Student’s t-test: (****) P < 0.001. (D) VEGFA level in CNV. Error bars indicate SEM (n = 10). One-way ANOVA and Tukey post-hoc tests: (****) P < 0.001. (E) Indel frequencies at the Vegfa target site in the RPE cells. Error bars indicate SEM (n = 5). Student’s t-test: (****) P < 0.001. (F) Indel frequencies at the Rosa26 target site in the RPE cells. Error bars indicate SEM (n = 5). Student’s t-test: (****) P < 0.001.

Figure 4. Subretinal injection of Cas9 RNPs targeting Vegfa reduces the area of laser-induced choroidal neovascularization (CNV) in a mouse model of age-related macular degeneration (AMD). (A) Mice with laser-induced CNV were treated with subretinal injection of the Vegfa-specific preassembled Cas9 RNP (Vegfa-RNP). After the retinal pigment epithelium (RPE) complex in the eye was flat-mounted, the CNV area was analyzed at day 7 post-injection. Genomic DNA isolated from the Cas9 RNP-injected area or from the opposite noninjected area (RNP-free area) was analyzed by deep sequencing. (B) Representative laser-induced CNV stained with isolectin B4 (IB4) in C57BL/6J mice injected with the Rosa26-specific Cas9 RNP (as a control) or the Vegfa-RNP. The yellow line demarcates the area of CNV.

A critical issue in therapeutic genome surgery is the target specificity of CRISPR-Cas9 nucleases. We investigated whether the Vegfa-RNP used in this study caused any off-target mutations in the mouse eye or in human cells. First, using Cas-OFFinder (Bae et al. 2014), we identified 20 potential off-target sites in the mouse genome that are most highly homologous to the Cas9 target site (Supplemental Table S2). Genomic DNA was isolated from the CNV-free, RPE complex in the eye was flat-mounted, the CNV area was analyzed at day 7 post-injection. Genomic DNA isolated from the Cas9 RNP-injected area or from the opposite noninjected area (RNP-free area) was analyzed by deep sequencing. VEGFA ELISA was performed at day 3 post-injection. Representative laser-induced CNV stained with isolectin B4 (IB4) in C57BL/6J mice injected with the Rosa26-specific Cas9 RNP (as a control) or the Vegfa-RNP. The yellow line demarcates the area of CNV. (C) The CNV area. Error bars indicate SEM (n = 15). Student’s t-test: (****) P < 0.001. (D) VEGFA level in CNV. Error bars indicate SEM (n = 10). One-way ANOVA and Tukey post-hoc tests: (****) P < 0.001. (E) Indel frequencies at the Vegfa target site in the RPE cells. Error bars indicate SEM (n = 5). Student’s t-test: (****) P < 0.001. (F) Indel frequencies at the Rosa26 target site in the RPE cells. Error bars indicate SEM (n = 5). Student’s t-test: (****) P < 0.001.

Next, we determined genome-wide off-target effects in the human genome rather than the mouse genome (Fig. 4A,B). Note that the target sequence of this particular Cas9 RNP is conserved in the human VEGFA gene. We assessed the human genome-wide specificity using Digenome-seq (Kim et al. 2015, 2016b), in which cell-free human genomic DNA is digested in vitro using the Vegfa-specific Cas9 RNP and then subjected to whole-genome sequencing. Uniform, rather than random, alignments of sequence reads at in vitro cleavage sites are computationally identified to provide a list of potential off-target sites. Digenome-seq using the Vegfa-RNP revealed 42 in vitro cleavage sites including the on-target site (Supplemental Table S3). To validate or invalidate these sites, we carried out targeted deep sequencing using genomic DNA isolated from Vegfa-RNP-transfected ARPE-19 cells. Although these sites were cleaved efficiently in vitro, off-target indels were not detected at these 41 cleavage sites above sequencing error rates (Fig. 4C). Use of Cpf1 (Zetsche et al. 2015; Kim et al. 2016a), Cas9 variants (Kleinstiver et al. 2016; Slaymaker et al. 2016), or modified gRNAs (Cho et al. 2014; Fu et al. 2014) with improved specificity may avoid this residual off-target effect, if necessary. Taken together, these results show that the Vegfa-RNP is highly specific in both mouse and human cells.
Another major concern for mutating the Vegfa gene for the treatment of AMD is its trophic role in the eye. Cone dysfunction is the most significant change and is observed 3 d after conditional deletion of the Vegfa gene in mouse RPE (Kurihara et al. 2012). Note, however, that the Vegfa gene was mutated locally at the site of the RNP injection in our study. We evaluated the integrity of cone opsin at day 7, rather than day 3, post-injection and found that no cone dysfunction had occurred (Supplemental Fig. S4).

**Discussion**

In this study, we showed that genome surgery using Cas9 RNPs has the potential for local, rather than systemic, treatment for non-genetic diseases such as AMD. Unlike previous studies involving RNA-guided genome editing in vivo to correct genetic defects, this report is focused on inactivating a disease-causing wild-type gene. This approach can broaden the scope of druggable targets from several protein families such as kinases, ion channels, and G protein-coupled receptors to any protein-coding or noncoding genes.

We believe that eye diseases are well-suited for in vivo genome editing using Cas9 RNPs. Because of its compartmented anatomy, subretinal injection is an optimized technique to deliver Cas9 RNPs into RPE cells for the local treatment. The laser-induced CNV model in mice that was used in this study is not suitable for multiple injection of Cas9 RNPs, because CNV formation peaks ~2 wk after laser treatment and then slightly regressed over time. For multiple injection studies, large animal models such as nonhuman primates should be considered. In human or nonhuman primates, subretinal injection of RNPs in a volume of 100–150 µL would be enough to cover choroidal neovascularization. We envision that genome surgery is not just a metaphor but can be a graphic description of “operations” in the near future by which surgeons or physicians use Cas9 RNPs as microscalps to cut and paste disease-causing genetic elements in patients.

**Methods**

**Data reporting**

No statistical methods were used to predetermine sample size for in vitro and in vivo experiments. The investigators were not blinded to allocation during in vivo experiments, but single-blinded to the outcome assessment, specifically measurement of the CNV area.

**Preparation of Cas9 RNPs**

Purified Cas9 protein was purchased from ToolGen, Inc. sgRNAs were generated by in vitro transcription using T7 polymerase (New England BioLabs) according to the manufacturer’s protocol. Briefly, templates for sgRNA were generated by annealing and extension of two complementary oligonucleotides (Supplemental Table S4). Templates were incubated with T7 RNA polymerase in reaction buffer (40 mM Tris-HCl, 20 mM MgCl₂, 2 mM spermidine, 1 mM DTT, pH 7.9), including NTPs (Jena Bioscience) and RNase inhibitor (New England BioLabs) for 16 h at 37°C. Transcribed sgRNAs were incubated with DNase I (New England BioLabs) for 6 min at 37°C. sgRNAs were purified using RNeasy MiniElute Cleanup kit (Qiagen) and quantified using NanoDrop (Thermo Fisher Scientific). Purified sgRNAs (65 µg) were incubated with CIP (1000 units) (Alkaline Phosphatase, New England BioLabs) for the removal of 3-phosphate for 1 h at 37°C.
purified again using the RNeasy MinElute Cleanup kit (Qiagen) and quantified using NanoDrop (Thermo Fisher Scientific). We also tested cell viability and indel efficiency using all Cas9 protein and sgRNA stocks, and high efficiency Cas9 protein and sgRNA stocks were used for in vivo eye injections.

Cy3-labeled Cas9 protein purification
After transformation of the pET28-NLS-Cas9 vector into E. coli strain BL21 (DE3), Cas9 protein expression was induced for 12 h at 20°C, with 0.5 mM isopropyl-β-D-1-thiogalactopyranoside (IPTG). The bacterial cells were lysed by sonication; after centrifugation at 20,000g for 30 min, the soluble lysate was mixed with NTA beads (Qiagen), and Cy3 dye (GE Healthcare) was added at a 1:10 ratio (protein:dye molecules). The mixture was incubated overnight (>12 h) in 4°C in the dark. Cy3-labeled Cas9 was eluted with elution buffer (50 mM Tris-HCl [pH 7.6], 150–500 mM NaCl, 10–25% glycerol, 0.2 M imidazole) and dialyzed against dialyzing buffer (20 mM HEPES pH 7.5, 150 mM KCl, 1 mM DTT, 10% glycerol). The purified Cy3-labeled Cas9 protein was concentrated using an Ultracel 100K cellulose column (Millipore). The purity of the Cy3-labeled Cas9 protein was determined by SDS-PAGE. The Cy3 labeling efficiency was measured by comparing the absorption spectra of the Cas9 protein (280 nm) and the conjugated Cy3 labeling efficiency was measured by comparing the absorption spectra of the Cas9 protein (280 nm) and the conjugated Cy3 dye molecule.

Cell culture and transfection
NIH3T3 (ATCC CRL-1658) and ARPE-19 (ATCC CRL-2302) cell lines were cultured in Dulbecco’s Modified Eagle Medium (DMEM) supplemented with 10% BCS or FBS at 37°C in a humidified atmosphere containing 5% CO2. NIH3T3 and ARPE-19 cells were not authenticated or tested for mycoplasma contamination. One day before transfection, NIH3T3 and ARPE-19 cells were seeded into 24-well plates at 2 x 104 cells per well, with each well containing 250 µl growth medium lacking antibiotics. For plasmid delivery, cells were transfected with Cas9 (1 µg) and sgRNA (1 µg) expression plasmids using Lipofectamine 2000 (Thermo Fisher Scientific) according to the manufacturer’s protocol. For RNP delivery, Cas9 protein (4 µg) was incubated with sgRNA (2.25 µg) for 5 min at room temperature, after which 50 µl Opti-MEM (Thermo Fisher Scientific) and 1 µl Lipofectamine 2000 (Thermo Fisher Scientific) were added. After 10 min, the RNP mixture was added to cells in the 24-well plates described above. Cells were harvested 48 h after transfection and analyzed using the T7E1 assay, targeted deep sequencing, and qPCR. For VEGFA expression in confluent RPE cells, ARPE-19 cells were maintained in DMEM/F12 containing 1% FBS after reaching confluency to allow formation of a polarized epithelial layer for the experiments (Park et al. 2015b). ARPE-19 cells in 12-well plates were transfected with 8 µg of Cas9 protein, 4.5 µg of sgRNA, and 3 µl of Lipofectamine 2000. Two days after transfection, the transfection growth medium (DMEM + 1% FBS) was gently replaced with 0.5 mL of fresh serum-free medium. After 16 h, cells and media were harvested and analyzed using targeted deep sequencing, qPCR, and ELISA.

Cy3-labeled Cas9 RNP imaging and counting
One day after transfection, cells were fixed in 4% PFA for 10 min at room temperature and then stained with 4’, 6-diamidino-2-phenylindole (DAPI, 1µg/mL; Sigma Aldrich) for 15 min at room temperature. Cells were visualized with a confocal microscope (LSM510, Carl Zeiss) at a magnification of 630x. The scanning parameters were as follows: scaling (x = 0.14 µm/pixel, y = 0.14 µm/pixel, z = 1 µm/pixel), dimensions (x = 1024, y = 1024, z = 6, channels: 3, 12-bit) with objective C-Apochromat 63x/1.20W Korr UV-VIS-IR. Cy3 positive nuclei were counted using ZEN 2 software (black edition, Ver 10.0, Carl Zeiss). To quantify the frequency of Cy3 positive nuclei, we counted the total number of cells and the number of cells with Cy3 staining in the nucleus in a field of view at a magnification of 630x and calculated the average percentage of Cy3 positive nuclei over four fields of view (n = 3).

T7E1 assay
Genomic DNA was isolated from cells and tissues using a DNaseasy Tissue Kit (Qiagen) according to the manufacturer’s protocol. After target sites were amplified using PCR, the products were de-natured and annealed using a thermal cycler. A list of primers used can be found in Supplemental Table S5. Annealed PCR products were incubated with T7 endonuclease I (ToolGen, Inc.) for 25 min at 37°C and analyzed by agarose gel electrophoresis.

Targeted deep sequencing
On-target and potential off-target regions were amplified from genomic DNA using Phusion polymerase (Thermo Fisher Scientific). The PCR amplicons were subjected to paired-end sequencing using an Illumina MiSeq at LAS, Inc. A list of primers used can be found in Supplemental Tables S6, S7, and S8. Indels around the site 3 bp upstream of the PAM sequence were considered to be mutations resulting from Cas9 RNP activity.

RNA extraction and qPCR
Total RNA was isolated from NIH3T3 and ARPE-19 cells using an easy-spinTM Total RNA extraction Kit (iNBRON) according to the manufacturer’s protocol. Two hundred fifty nanograms of RNA was then reverse transcribed using SuperScript II (Invitrogen). Quantitative PCR was performed using SYBR Green (KAPA) with the following primers: mouse Vegfa, 5′-ACGTCAGAGGACAACATCAG-3′ (forward), 5′-CTGCTTCTTCGTTGTCATTCC-3′ (reverse); human Vegfa-1, 5′-CGAGTACATCTTCGAAGG-3′ (forward), 5′-GGTGGTTCACACCCATCAACAAA-3′ (reverse); human Vegfa-2, 5′-AGAAGGAGGGCGCCAGAAT-3′ (forward), 5′-CACAGATTGGCTAGAGTGTA-3′ (reverse); and human Gapdh, 5′-CAATGCTCCTCATTGACC-3′ (forward), 5′-TTGATTTGTGAGGGATCTCGG-3′ (reverse).

VEGFA ELISA using confluent ARPE-19 cells
For human VEGFA ELISA, serum-free supernatants were collected from Vegfa-specific Cas9 RNP-treated confluent ARPE-19 cell cultures after cells were incubated in serum-free medium for 16 h. Secreted VEGFA protein levels were measured using a human VEGF Quantikine ELISA Kit (DVE00, R&D systems) according to the manufacturer’s instructions.

In vitro cleavage of genomic DNA and Digenome sequencing
Genomic DNA was isolated from ARPE-19 cells (ATCC) with a DNaseasy Tissue Kit (Qiagen). In vitro cleavage of genomic DNA for Digenome sequencing was performed as described previously (Kim et al. 2015, 2016b). Briefly, genomic DNA (20 µg) was incubated with Cas9 protein (16.7 µg) and sgRNA (12.5 µg) in reaction buffer (100 mM NaCl, 50 mM Tris-HCl, 10 mM MgCl2, 100 µg/mL BSA, pH 7.9) for 3 h at 37°C. Cleaved genomic DNA was treated with RNase A (50 µg/mL, Sigma Aldrich) for 30 min at 37°C and purified with a DNaseasy Tissue Kit (Qiagen). Whole-genome and Digenome sequencing were performed as described previously (Kim et al. 2016b).
Animals

The care, use, and treatment of all animals in this study were in strict agreement with the ARVO “Statement for the Use of Animals in Ophthalmic and Vision Research” and the guidelines established by the Seoul National University Institutional Animal Care and Use Committee. Adult (6 wk old) male SPF C57BL/6j mice were used in the study. Mice were maintained under a 12 h dark-light cycle.

Subretinal injections

Subretinal injection was performed as previously described (Park et al. 2015c). Briefly, RNP’s composed of Cas9 protein (8 μg), sgRNA (4.5 μg), and Lipofectamine 2000 (20% v/v) were mixed in 2 μL of injection volume. RNP’s (2 or 3 μL) were injected into the subretinal space using a Nanojet syringe with a 33G blunt needle (World Precision Instruments, Inc.) under an operating microscope (Leica Microsystems, Ltd.). Subjects with retinal hemorrhage were excluded from the study.

Western blotting

To analyze RNP levels over time after in vivo RNP delivery, Western blotting of RPE complexes, obtained at 1 and 3 d post-injection, was performed. Samples containing an equal amount of protein (20 μg) were analyzed; Cas9 and beta-actin were detected with an anti-HA high affinity antibody (Roche, 3F10, 1:1000) and an anti-beta-actin antibody (Sigma Aldrich, A2066, 1:1000), respectively. ImageQuant LAS4000 (GE healthcare) was used for digital imaging.

Statistics

Data were analyzed with SPSS software version 18.0 (SPSS, Inc.). P-values were determined by an unpaired, two-sided Student’s t-tests or one-way ANOVA and Tukey post-hoc tests for multiple groups. Data are shown as mean with SEM.

Data access

The whole-genome sequencing and deep sequencing data from this study have been submitted to the NCBI Sequence Read Archive (SRA; https://www.ncbi.nlm.nih.gov/sra) under accession numbers SRX2487860, SRX1801343, and SRX1801344.

Advance online articles have been peer reviewed and accepted for publication but have not yet appeared in the paper journal (edited, typeset versions may be posted when available prior to final publication). Advance online articles are citable and establish publication priority; they are indexed by PubMed from initial publication. Citations to Advance online articles must include the digital object identifier (DOIs) and date of initial publication.
