We find that generic boundary conditions of the Weyl semimetal are dictated by only a single real parameter in the continuum limit. We determine how the energy dispersions (the Fermi arcs) and the wave functions of edge states depend on this parameter. Lattice models are found to be consistent with our generic observation. Furthermore, the enhanced parameter space of the boundary condition is shown to support a novel topological number.

1. Introduction

One of the important aspects of topological phases \cite{1,2} is that they bridge condensed matter physics and particle physics. Familiar and important concepts in particle physics, such as topological charges, quantum anomalies, and relativity, are completely translated to condensed matter physics, and their experimental realization flourishes and verifies the concept quite nontrivially. The interplay between the condensed matter physics and the particle physics is further expected to provide developments in these fields.

From the theoretical side, topological phases are classified by dimensions and discrete symmetries \cite{3,4}. The symmetries are important for the classification, as they are robust against deformations. In particular, at microscopic levels materials have lots of ways for their Hamiltonian to be deformed. However, if one is based on the topological properties that are determined by the discrete symmetries, the classification and the resultant phenomena are robust. This works even at a continuum limit where the detailed structure of the lattice Hamiltonian disappears. The outcome of the topological phases is the existence of a gapless edge mode, as a consequence of the renowned bulk–edge correspondence \cite{5–7}.

Particle physics Lagrangians are also written based on symmetries. Normally, particle physics Lagrangians have all possible terms allowed by the required symmetries, in the continuum limit. Then a natural question arises: what are all possible boundary conditions? This question is particularly important in view of the bulk–edge correspondence, because one typically assumes an open boundary condition in the study of topological phases.

Although to answer this question at the level of listing all possible lattice Hamiltonians with boundaries is far beyond our knowledge, we could approach the answer in the continuum limit. The continuum Hamiltonian is much easier to deal with, and we can ask how general the Hamiltonian
we have is. Furthermore, it is expected to capture the generic feature of all lattice systems that share
the same discrete symmetries as the continuum Hamiltonian.

In this paper, we focus on the 3D Weyl semimetal, which has recently been observed in experiments
[8–10] after theoretical predictions [11–17], and study the most generic boundary condition in the
continuum limit. We will see how a generic surface term in the Lagrangian can affect the edge
states of a Weyl fermion, in a Hamiltonian language—in other words, we will see how a generic
modification of the boundary conditions gives a change in the edge dispersions. The existence of the
discrete symmetries of a given Weyl semimetal is certainly explained by the topological number of the bulk
theory, but how the boundary conditions are related with the edge states, or so-called Fermi arcs, has
not been studied well in the literature.1 To look at genericity under a given symmetry is a particle
theory standpoint, which could serve as another new interplay between the two fields.

Our study is divided into two parts, the study of the continuum theory and a verification by lattice
models. On the continuum theory side, we start with the standard Hamiltonian with a single Weyl
cone, and consider the most general boundary condition, with resultant edge states. In particular, we
are careful with the allowed number of parameters. We also study dimensional reduction to 2D, at
which topological insulators of class A can be studied. On the lattice model side, a square lattice in
3D and its 2D reduction are considered.

Our main findings are summarized as follows:

○ The generic boundary condition of the 3D Weyl semimetal is dictated only by a single real
  parameter. At low energy, all edge states are labeled by the parameter.
○ The parameter describes how the edge dispersion is attached to the Weyl node.
○ The results of the lattice models are perfectly consistent with the continuum theory in the vicinity
  of the Weyl point.

In the course of our study, we also find novel properties of the Weyl semimetals:

○ Our results of the edge states are all consistent with the bulk–edge correspondence. In particular,
  we propose how to count the edge states for the Weyl semimetals.
○ A new topological structure emerges in the enhanced parameter space spanned by the boundary
  parameter and the two conserved momenta. The edge state carries the topological charge.

Our paper is organized as follows. In Sect. 2, we study the 3D Weyl semimetals and their generic
boundary conditions in the continuum limit. We derive the relations between energy dispersions, wave
functions of edge states, and the boundary conditions. We also study a dimensional reduction to 2D
topological insulators. In Sect. 3, we investigate lattice models and show the consistency with the
results obtained in the continuum limit. In Sect. 4, we check the bulk–edge correspondence. We further
propose how to count the edge states of the Weyl semimetals. In Sect. 5, we find a new topological
structure of the edge states in the enhanced parameter space of the boundary conditions. In the last
section, we summarize our paper. In the appendices, we provide two examples of generalization:
treatment of generic momentum-dependent boundary conditions, and the case with two parallel
boundaries, in the continuum limit of the model of the Weyl semimetals.

1 For generic boundary conditions for topological insulators, see Refs. [18,19]. For transitions from Weyl
semimetals to topological insulators, see Ref. [20].
2. Generic boundaries of 3D Weyl semimetals at continuum

We start with a generic Weyl semimetal in three spatial dimensions. Near the Weyl point, the Hamiltonian in the continuum limit is generically given by

\[ \mathcal{H} = p_1 \sigma_1 + p_2 \sigma_2 + p_3 \sigma_3. \] (1)

Here, the Weyl point sits at the origin of the three-dimensional momentum space. We are interested in the most generic boundary conditions and the spectra of this system. The states are energy eigenstates, subject to the following boundary condition:

\[
\begin{align*}
\mathcal{H} \psi & = \epsilon \psi \\
(M + 1) \psi & \big|_{x_3=0} = 0,
\end{align*}
\] (2) (3)

where we put a boundary at \( x_3 = 0 \), so the material is in the spatial region \( x_3 \geq 0 \). A real constant \( \epsilon \) is the energy eigenvalue, and \( M \) is a generic \( 2 \times 2 \) complex constant matrix. (See Appendix A for generic momentum-dependent boundary conditions.)

The Hamiltonian can effectively describe a two-band system that has a degeneracy at the Weyl point with a definite chirality. It captures the topological nature around the Weyl point, and is equivalent to the Hamiltonian of a Weyl fermion in three spatial dimensions. The boundary condition needs to be of the form Eq. (3), since at the boundary two components of \( \psi \) are related to each other through the boundary condition. The matrix \( M \) reflects the arbitrariness in the choice of the boundary condition; one can think of infinitely many kinds of boundaries, starting from just a slicing of the material, to putting various chemical layers on top of the boundary surfaces, such as hydrogen/nitrogen termination or oxidization.

We solve the equations above, which give energy dispersion relations and wave functions. We find that the most generic boundary condition (3) is parameterized only by a single real constant \( \theta_+ \in [0, \pi) \).

2.1. Parameterizing the generic boundary condition

In this subsection we explore all the requirements for the boundary condition matrix \( M \) in Eq. (3) and parametrize it. It turns out that \( M \) is parameterized only by two real parameters, and furthermore, the boundary condition (3) needs only one of them. These result from a self-conjugacy of the Hamiltonian (1) and the requirement that \( M \) needs to have the eigenvalue \(-1\): the combination \( M + 1 \) needs to have a zero eigenvalue for a nontrivial solution satisfying the boundary condition (3) to exist.

2.1.1. Self-conjugacy of the Hamiltonian

In general, \( M \) is a \( 2 \times 2 \) complex matrix and has four complex degrees of freedom (d.o.f.), that is, eight real d.o.f. are there. We parametrize it as

\[ M = a_0 \mathbf{1}_2 + a_i \sigma_i \] (4)

with complex coefficients \( a_0 = A_0 + iB_0 \) and \( a_i = A_i + iB_i \in \mathbb{C} \), where \( i = 1, 2, 3 \).

We need our Hamiltonian (1) to be self-conjugate, which gives a constraint on the boundary condition. See also Ref. [21]. The self-conjugacy condition of the Hamiltonian is

\[ \langle \mathcal{H} \psi_1 | \psi_2 \rangle = \langle \psi_1 | \mathcal{H} \psi_2 \rangle, \] (5)
for arbitrary normalizable $\psi_1$ and $\psi_2$. When we explicitly write the two inner products above as an integration, we find a surface difference between the right-hand side and the left-hand side, which must vanish:

$$[(\sigma_3 \psi_1) \dagger \psi_2]|_{x_3=0} = 0. \quad (6)$$

Applying the boundary condition (3) onto this equation gives

$$[(\sigma_3 \psi_1) \dagger \psi_2]|_{x_3=0} = -\frac{1}{2}[(\sigma_3 M \psi_1) \dagger \psi_2]|_{x_3=0} - \frac{1}{2}[(\sigma_3 \psi_1) \dagger M \psi_2]|_{x_3=0} = 0,$$

which is satisfied for any choice of $\psi_1$ and $\psi_2$ only when

$$M^\dagger \sigma_3 = -\sigma_3 M. \quad (7)$$

This is required by the self-conjugacy of the Hamiltonian. Equation (7) removes four real d.o.f. of $M$:

$$0 = M^\dagger \sigma_3 + \sigma_3 M = a_0^* \sigma^3 a_0^I + \sigma^3 \sigma^I a_I$$

$$= 2A_0 \sigma_3 + 2A_2 I_2 + 2iB_1 \sigma_2 - 2iB_2 \sigma_1, \quad (8)$$

and results in

$$A_0 = A_3 = B_1 = B_2 = 0. \quad (9)$$

So we are left with the boundary condition matrix with four real parameters,

$$M = A_1 \sigma_1 + A_2 \sigma_2 + iB_0 I_2 + iB_3 \sigma_3. \quad (10)$$

2.1.2. Eigenvalues of $M$

The boundary condition (3) can be regarded as an eigenequation for matrix $M$. Substituting Eq. (9) into the determinant of Eq. (3),

$$\det(M - \lambda) = 0, \quad (11)$$

we get

$$\lambda_{\pm} = iB_0 \pm \sqrt{A_1^2 + A_2^2 - B_3^2}. \quad (12)$$

The boundary condition requires $M$ to have a real eigenvalue $-1$, which gives two constraints:

$$B_0 = 0, \quad (13)$$

$$\pm \sqrt{A_1^2 + A_2^2 - B_3^2} = -1. \quad (14)$$
As a result, the generic boundary condition matrix should be written as

\[ M = A_1 \sigma_1 + A_2 \sigma_2 + iB_3 \sigma_3, \quad A_1^2 + A_2^2 - B_3^2 = 1. \]

(15)

Consequently, \( M \) is parametrized by two real parameters. We can choose

\[
\begin{cases}
  A_1 = \cos \theta \cosh \chi \\
  A_2 = \sin \theta \cosh \chi \\
  B_3 = \sinh \chi
\end{cases}
\]

(16)

for parameterizing the matrix, with which the boundary condition can be written as

\[
\left( \begin{array}{cc}
  \text{sech} \chi + i \tanh \chi & \cos \theta - i \sin \theta \\
  \cos \theta + i \sin \theta & \text{sech} \chi - i \tanh \chi
\end{array} \right) \psi \bigg|_{x^3=0} = 0.
\]

(17)

Defining \( \cos \theta' = \text{sech} \chi \) and \( \sin \theta' = \tanh \chi \), and changing variables:

\[
\theta' = \theta_+ + \theta_-
\]

\[
\theta = \theta_+ - \theta_-,
\]

we find that Eq. (17) becomes

\[
\left( \begin{array}{cc}
  e^{i\theta'} & e^{-i\theta'} \\
  e^{i\theta} & e^{-i\theta'}
\end{array} \right) \psi \bigg|_{x^3=0} = 0.
\]

(18)

Noting the relation

\[
\left( \begin{array}{cc}
  e^{i\theta'} & e^{-i\theta'} \\
  e^{i\theta} & e^{-i\theta'}
\end{array} \right) = \left( \begin{array}{cc}
  e^{i\theta'} \\
  e^{i\theta}
\end{array} \right) \left( \begin{array}{cc}
  1 & e^{-2i\theta_+}
\end{array} \right),
\]

(19)

the boundary condition is recast to the following simple form:

\[
\left( \begin{array}{cc}
  1 & e^{-2i\theta_+}
\end{array} \right) \psi \bigg|_{x^3=0} = 0.
\]

(20)

It is surprising that for the boundary condition we actually need only a single real parameter \( \theta_+ \). So we conclude that the most generic boundary condition is just dictated by a single real parameter.

Equation (20) tells us further that, at the boundary, two components of the fermion need to have identical magnitude, and the relative phase between them is determined by \( \theta_+ \). This is true for the edge modes as well as the bulk modes.

For our later purpose, we determine here the range of the parameter \( \theta_+ \). First, from the definition of \( \theta \) and \( \theta' \), we find that they live on a region

\[ 0 < \theta \leq 2\pi, \quad 0 < \theta' \leq \pi. \]

(21)

Note that \( \sin \theta' = \text{sech} \chi \geq 0 \). Then one notices that the region can equally be covered by

\[ 0 < \theta \leq 2\pi, \quad 0 \leq \theta + \theta' \leq 2\pi. \]

(22)

Hence, the smallest necessary region for \( \theta_+ \) is given by

\[ 0 \leq \theta_+ \leq \pi. \]

(23)

\( \theta_+ = 0 \) and \( \theta_+ = \pi \) are the same configuration up to some adjustment of \( \theta_- \) which does not appear in the boundary condition itself.
2.2. Lagrangian formulation

Since Lagrangian formulation sometimes works more easily, we present here an equivalent Lagrangian formulation of what we have seen in terms of the Hamiltonian. In fact, we find that the condition (7) shows up naturally in the Lagrangian formulation. Let us describe a generic and consistent boundary condition of a Weyl semimetal in 1+3 spacetime dimensions. The metric convention is chosen as $\eta_{\mu\nu} = \text{diag}(+,-,-,-)_{\mu\nu}$.

The bulk Lagrangian (for a right-handed Weyl fermion) is written as

$$L = \frac{i}{2} \psi^\dagger \sigma^\mu (\overleftarrow{\partial}_\mu - \overrightarrow{\partial}_\mu) \psi,$$

where $\sigma^\mu = (1, \sigma_1, \sigma_2, \sigma_3)$. The Dirac equation is

$$\sigma^\mu \partial_\mu \psi = 0,$$

which can be rewritten as

$$[i\partial_0 + i\sigma_i \partial_i] \psi = 0,$$

where $i = 1, 2, 3$. So the Hamiltonian is $i\partial_0 = \mathcal{H}$,

$$\mathcal{H} = p_1\sigma_1 + p_2\sigma_2 + p_3\sigma_3,$$

which is the standard Hamiltonian of the Weyl semimetal near the Weyl cone.

Let us introduce a surface term in the Lagrangian, for deriving the boundary condition. The total action is

$$S = \int_{x^3 \geq 0} d^3x \frac{i}{2} \psi^\dagger \sigma^\mu (\overleftarrow{\partial}_\mu - \overrightarrow{\partial}_\mu) \psi + \frac{1}{2} \int_{x^3 = 0} d^2x \psi^\dagger N \psi.$$

The first term is the Weyl Lagrangian. The second integral is with a Hermitian matrix $N$. A variation $\psi \to \psi + \delta\psi$ and $\psi^\dagger \to \psi^\dagger + \delta\psi^\dagger$ provides equations at the surface $x^3 = 0$ as

$$\left[-i\psi^\dagger \sigma_3 + \psi^\dagger N\right] \delta\psi = 0, \quad \delta\psi^\dagger [i\sigma_3 \psi + N\psi] = 0.$$

For this to be valid for arbitrary $\delta\psi$ and $\delta\psi^\dagger$, we find

$$-i\psi^\dagger \sigma_3 + \psi^\dagger N = 0, \quad i\sigma_3 \psi + N\psi = 0$$

at the boundary $x^3 = 0$. These two equations are complex-conjugate to each other. If we write $N = i\sigma_3 M$, then

$$(M + 1)\psi \bigg|_{x^3 = 0} = 0.$$

The Hermiticity condition $N = N^\dagger$ is now written by $M$ as

$$M^\dagger \sigma_3 + \sigma_3 M = 0,$$

which is found to be equivalent to the Hamiltonian conjugacy constraint on $M$, (7). Note that this condition follows from the Hermiticity of $N$, that is, the Hermiticity of the surface Lagrangian.
So, in the end, we found that the boundary condition is dictated by a boundary “mass” term with a Hermitian matrix $N$,

$$\frac{1}{2} \int d^3x \, \delta(x^3) \, \psi \dagger N \psi .$$  \hspace{1cm} (33)

The most generic boundary condition is given by a constant Hermitian matrix $N$, and that is physically natural.

### 2.3. Generic edge modes and dispersions

Since the Weyl fermion possesses a topological number, we expect the existence of the edge-localized modes when we introduce a boundary $x^3 = 0$. In this subsection we look for an edge mode solution of the energy eigenvalue problem. With the most generic boundary condition (20) we obtained, we find a dispersion relation and the wave function of the edge mode, which are completely specified by $p_1, p_2$, and $\theta_+$.

#### 2.3.1. Solving the eigenstate equation

Now we look for an edge mode solution to the eigenvalue equation (2). With an explicit two-component notation,

$$\psi = \begin{pmatrix} \xi \\ \eta \end{pmatrix} ,$$  \hspace{1cm} (34)

the eigenstate equation (2) can be written as

$$\begin{pmatrix} -i \partial_3 - \epsilon & p_1 - ip_2 \\ p_1 + ip_2 & i \partial_3 - \epsilon \end{pmatrix} \begin{pmatrix} \xi \\ \eta \end{pmatrix} = 0 .$$  \hspace{1cm} (35)

This equation can be reorganized into two independent second-order differential equations:

$$\begin{pmatrix} p_1^2 + p_2^2 - \epsilon^2 - \partial_3^2 \end{pmatrix} \begin{pmatrix} \xi \\ \eta \end{pmatrix} = 0 .$$  \hspace{1cm} (36)

We look for the modes localized at the boundary. For the edge modes, we need

$$\alpha^2 \equiv p_1^2 + p_2^2 - \epsilon^2 > 0 ,$$  \hspace{1cm} (37)

then the corresponding solutions required by the normalizability are

$$\begin{pmatrix} \xi \\ \eta \end{pmatrix} = e^{-\alpha(x^3)} \begin{pmatrix} \xi_0 \\ \eta_0 \end{pmatrix} ,$$  \hspace{1cm} (38)

where $\xi_0$ and $\eta_0$ have no dependence on $x^3$. These are the edge modes, and in the following we determine the dispersion $\epsilon(p_1, p_2)$ and the relation between the components $\xi_0$ and $\eta_0$.

#### 2.3.2. Dispersion relation

We combine the results from eigenvalue equation (2) and boundary condition (3) for edge eigenmodes. Using the boundary condition (20), the edge state wave function is written as

$$\begin{pmatrix} \xi \\ \eta \end{pmatrix} = e^{-\alpha(x^3)} \begin{pmatrix} 1 \\ e^{2i\theta_+} \end{pmatrix} ,$$  \hspace{1cm} (39)
up to a normalization factor and a phase. Substituting this into the Hamiltonian eigenequation (35), we obtain

$$(i\alpha - \epsilon) + (p_1 - ip_2)e^{2i\theta_+} = 0.$$  \hspace{1cm} (40)

Substituting Eqs. (37) and (38) into Eq. (35), we get one independent equation:

$$(i\alpha - \epsilon)\xi_0 + (p_1 - ip_2)\eta_0 = 0.$$  \hspace{1cm} (41)

Looking at the real and the imaginary parts of this equation, we easily find

$$\epsilon = -p_1 \cos 2\theta_+ - p_2 \sin 2\theta_+,$$  \hspace{1cm} (42)

$$\alpha = p_1 \sin 2\theta_+ - p_2 \cos 2\theta_+.$$  \hspace{1cm} (43)

The first equation is the dispersion relation of the edge states. It is linear with respect to $p_1$ and $p_2$, and the speed of light is now anisotropic.

Another way to look at the equations is as follows: the Fermi arc is defined by $\epsilon = 0$ for a vanishing chemical potential. Then the equations above determine a relation between $p_1$ and $p_2$, which is nothing but the orientation of the Fermi arc emanating from the projected Weyl point $p_1 = p_2 = 0$.

We can rewrite the above two equations in a compact way:

$$\begin{pmatrix} \epsilon \\ \alpha \end{pmatrix} = - \begin{pmatrix} \cos 2\theta_+ & \sin 2\theta_+ \\ -\sin 2\theta_+ & \cos 2\theta_+ \end{pmatrix} \begin{pmatrix} p_1 \\ p_2 \end{pmatrix}.$$  \hspace{1cm} (44)

Interestingly, Eq. (44) shows that what the boundary does is only rotating the momenta $(p_1, p_2)$ into $(\epsilon, \alpha)$, the energy and the inverse of the edge mode decay width (penetration depth). For fixed $p_1$ and $p_2$, we can regard the pair $(\epsilon, \alpha)$ as a vector rotating around the origin by $2\theta_+$. When the absolute value of $\epsilon$ becomes large, $\alpha$ becomes small, then the penetration depth is large. On the other hand, when the absolute value of $\epsilon$ becomes small, $\alpha$ becomes large and then the penetration depth is small. This coincides with the intuition that the wave function penetration measured from the location of the boundary increases for larger energy of the edge mode.

Plotting the dispersion relation, we actually see in Fig. 1 that the edge dispersion is rotated against the $(p_1, p_2)$ axes by the change of the boundary parameter $\theta_+$.

### 2.3.3 Wave function of edge modes

Let us finally write the wave function of the edge states. We have already used up most of the information and are left with the normalization condition only, with which we can determine the wave function completely. Substituting Eq. (38) to the normalization condition

$$\int_0^\infty dx^3 \psi^\dagger \psi = 1,$$  \hspace{1cm} (45)

we obtain a constraint

$$|\xi_0|^2 + |\eta_0|^2 = 2\alpha.$$  \hspace{1cm} (46)

With the second equation of (40), the boundary condition, we can see that the two components should have the same magnitude with a difference in their phases. Combined with Eq. (46), they are
Fig. 1. Figures $a$, $b$, $c$, $d$, $e$ respectively represent the energy dispersions of the bulk states and the edges states, for $2\theta_+ = \pi/2, \pi/4, 0, -\pi/4, -\pi/2$.

determined up to an irrelevant overall phase:

$$\begin{pmatrix} \xi_0 \\ \eta_0 \end{pmatrix} = \sqrt{\alpha} \begin{pmatrix} e^{-2i\theta_+} \\ -1 \end{pmatrix}. \quad (47)$$

So the general edge mode wave function is

$$\psi(x^3) = \sqrt{\alpha} \exp(-\alpha x^3) \begin{pmatrix} e^{-2i\theta_+} \\ -1 \end{pmatrix}, \quad (48)$$

$$\alpha = p_1 \sin 2\theta_+ - p_2 \cos 2\theta_+.$$

Note that the edge modes exist only in a limited region of the momentum space, since we need to require $\alpha > 0$. The linear inequality $\alpha > 0$ specifies half of the momentum space, in which the dispersion exists, see Fig. 1.

In the limit $\alpha = 0$, that is, on the line $p_1 \sin 2\theta_+ - p_2 \cos 2\theta_+ = 0$ in the momentum space, the edge mode approaches a non-normalizable mode, which is a constant wave function in the $x^3$ space. It corresponds to the $p_3 = 0$ bulk mode, whose dispersion is $\epsilon = \pm \sqrt{p_1^2 + p_2^2}$. In fact, the edge dispersion (42) is identical to that under the condition $\alpha = 0$. Therefore we have a consistent picture for any value of $\theta_+$: when the edge mode approaches a non-normalizable state in the momentum space, it is consistently and continuously absorbed into the bulk modes. In Fig. 1, we find explicitly that the edge dispersion surface has its boundary on the bulk dispersion surface.

We would like to make one comment about how we could modify the range of $\alpha$ in different setups. If we introduce two boundaries that are parallel to each other, then the condition of the positivity of $\alpha$ does not apply, as the wave functions are normalizable even for a negative value of $\alpha$. We demonstrate the calculation in Appendix B.
In summary, we find that the dispersion of the edge state is attached to the bulk Weyl cone in such a way that (i) the edge dispersion is tangential to the Weyl cone, and (ii) the edge dispersion ends at the touching line on the Weyl cone.

2.4. Reduction to 2D

It is important that the analysis given above can be consistently translated to a 2D topological insulator of class A. It is just a dimensional reduction of the previous Hamiltonian from 3D to 2D, by a replacement of one of the momenta—$p_2$ with a constant mass parameter $m$. This means that we can study the most generic boundary condition of the class A topological insulator in the continuum limit, and its consequence in the edge dispersions.

By dimensional reduction, the Hamiltonian of the 2D gapped fermion is given as

$$H = p_1 \sigma_1 + m \sigma_2 + p_3 \sigma_3. \quad (49)$$

The analysis of the boundary condition we had before for the Weyl semimetals does not change, since it is just a renaming of $p_2$. So it is identical to our previous (20):

$$\left( \begin{array}{c} 1 \\ e^{-2i\theta_+} \end{array} \right) \psi \bigg|_{x^3=0} = 0. \quad (50)$$

The dispersion relation $\epsilon$ and the inverse decay width $\alpha$ are given simply by a replacement of $p_2$ with $m$:

$$\left( \begin{array}{c} \epsilon \\ \alpha \end{array} \right) = -\left( \begin{array}{cc} \cos 2\theta_+ & \sin 2\theta_+ \\ -\sin 2\theta_+ & \cos 2\theta_+ \end{array} \right) \left( \begin{array}{c} p_1 \\ m \end{array} \right). \quad (51)$$

The same is applied for the edge mode wave function:

$$\psi(x^3) = \sqrt{\alpha} \exp(-\alpha x^3) \left( \begin{array}{c} e^{-2i\theta_+} \\ -1 \end{array} \right). \quad (52)$$

Figure 2 shows the bulk and the edge dispersions for various choices of the boundary parameter $\theta_+$. Since our procedure is just replacing the momentum $p_2$ by a constant $m$, it amounts to choosing a plane of constant $p_2$ in the 3D Weyl semimetal dispersion given in Fig. 1. Taking a cross section, we find that the 3D Weyl dispersion and the edge dispersion reduce to dispersions of the gapped bulk and the linear edge modes in 2D.

It is interesting that the rotation $2\theta_+$ in the $(p_1, p_2)$ plane for the 3D Weyl semimetals can inherit its nature in the 2D topological gapped system in a nontrivial manner. The form of the edge dispersion, as a function of $p_1$, looks quite nontrivial in Fig. 2. For some special choice of the value $\theta_+ = \pi/2$, the edge dispersion eventually disappears. For some other values of $\theta_+$, the edge dispersion becomes a flat band.

By taking a massless limit $m = 0$ for the bulk system, the edge dispersion is simply given by

$$\epsilon = -p_1 \cos(2\theta_+). \quad (53)$$

The existence condition of the edge state is $p_1 \sin 2\theta_+ (= \alpha) > 0$. So the edge dispersion, which is a half-line, emanates linearly from the Dirac point of the bulk by the slope $\cos 2\theta_+$, where the parameter $\theta_+$ can range $0 \leq \theta_+ < \pi$. 

10/29
Fig. 2. Taking a constant $p_2$ cross section in the dispersion relation of the 3D case, we obtain the dispersion relation of the 2D topological material, both the gapped bulk states and the edge states. The red straight half-lines are the edge dispersions of the 2D topological insulator. For each set of figures, the right figure is the cross section while the left figure is the original view of the 3D Weyl semimetals. Figures $a$ to $h$ have the boundary parameter $2\theta_1 = \pi, \frac{3}{2}\pi, \pi/2, \pi/4, 0, -\pi/4, -\pi/2, -\frac{3}{2}\pi$, respectively.

3. Lattice models

The effective model study shown above exhibits an interesting behavior of the edge state depending on the boundary condition. Let us then show how such an argument on the boundary condition is realized in lattice models with tight-binding Hamiltonians.

3.1. Boundary condition for the discretized model

In the effective continuum theory the boundary condition requires some conditions due to the self-conjugacy of the Hamiltonian. Following this argument, we consider the boundary condition with the discretized lattice model.
First of all, we cannot directly apply the continuum theory argument to the lattice model because this argument relies on integration by parts—we need to replace the differential operator with a difference operator which does not satisfy the Leibniz rule. We have to be careful about dealing with the boundary of the discrete lattice system.

To demonstrate how the self-conjugacy characterizes the boundary condition, we consider a discrete model defined on a finite one-dimensional lattice labeled by \( n = 1, \ldots, N \). The self-conjugate operator we consider here is \( \mathcal{H} = -i\sigma \nabla \), where \( \sigma \) is a Hermitian matrix to be taken as a Pauli matrix, and the difference operator is defined by

\[
\nabla \psi_n = \psi_{n+1} - \psi_n, \quad (54)
\]
\[
\nabla^{\dagger} \psi_n = \psi_{n-1} - \psi_n. \quad (55)
\]

This difference operator reduces to the differential operator in the continuum limit, so that the operator becomes the standard Dirac Hamiltonian \( \mathcal{H} \rightarrow -i\sigma \partial_x \) in the limit. Since they are related to each other, \( i\nabla^{\dagger} \psi_{n+1} = -i\nabla \psi_n \), this is locally self-conjugate. However, as discussed before, we need to take care of the boundary: The discrete Dirac Hamiltonian is self-conjugate up to the boundary term

\[
\sum_{n=1}^{N} \psi_n^{\dagger} (-i\sigma \nabla \psi_n) = \sum_{n=1}^{N} \left( i\sigma \nabla^{\dagger} \psi_n \right)^{\dagger} \psi_n + \psi_0^{\dagger} (i\sigma) \psi_1 - \psi_N^{\dagger} (i\sigma) \psi_{N+1}, \quad (56)
\]

where we introduced auxiliary fields \( \psi_0 \) and \( \psi_{N+1} \). The second line shows the surface term in this case, and the self-conjugacy of the Hamiltonian requires that this part should vanish:

\[
\psi_0^{\dagger} (i\sigma) \psi_1 - \psi_N^{\dagger} (i\sigma) \psi_{N+1} = 0. \quad (57)
\]

We have two possibilities to solve this condition. The first is the periodic boundary condition \( \psi_n = \psi_{n+1} \) for all \( n \in \{1, \ldots, N\} \). Then these two terms cancel each other. The second is the situation that both terms vanish independently, which corresponds to the open boundary condition.

Let us focus on the first term \( \psi_0^{\dagger} (i\sigma) \psi_1 \), and apply the boundary condition that is analogous to that considered in continuum theory,

\[
(M + 1) \psi \bigg|_{n=0,1} = 0. \quad (58)
\]

We remark that this boundary condition is assigned to both \( \psi_{n=0} \) and \( \psi_{n=1} \), although the former is just an auxiliary field. If this matrix \( M \) satisfies

\[
M^{\dagger} \sigma + \sigma M = 0, \quad (59)
\]

the first term vanishes due to the same argument given in the continuum theory shown in Sect. 2.1. We also apply a similar condition to the opposite boundary \( n = N, N + 1 \) with a matrix \( M' \), which is not necessarily the same as \( M \) as long as it satisfies the condition (59).

### 3.2 3D Weyl semimetal model

We then incorporate the boundary condition into the Weyl semimetal model on a lattice. We consider the Hamiltonian defined on a 3D lattice,

\[
H = \sum_n \psi_n^{\dagger} \mathcal{H} \psi_n, \quad (60)
\]
Fig. 3. The energy band spectrum of the bulk Hamiltonian (62) with $p_3 = 0$ and $c = 1$. The Weyl points are at $(p_1, p_2) = (\pm \pi/2, 0)$.

where $n$ is a three-dimensional vector $n = (n_1, n_2, n_3) \in \mathbb{Z}^3$, and the operator is given by

$$
\mathcal{H} = \frac{1}{2} \sigma_1 \left( \nabla_1 + \nabla_1^\dagger - \nabla_2 - \nabla_2^\dagger + 2c \right) - i \frac{1}{2} \sigma_2 \left( \nabla_2 - \nabla_2^\dagger \right) - i \frac{1}{2} \sigma_3 \left( \nabla_3 - \nabla_3^\dagger \right).
$$

In the Fourier basis, the Bloch Hamiltonian is obtained as

$$
\mathcal{H}(p) = \sigma_1 (\cos p_1 - \cos p_2 + c) + \sigma_2 \sin p_2 + \sigma_3 \sin p_3,
$$

which exhibits Weyl points at

$$
(p_1, p_2, p_3) = \begin{cases} 
(\cos^{-1}(1 - c), 0, 0 & \pi) & (0 \leq c \leq 2) \\
(\cos^{-1}(-1 - c), \pi, 0 & \pi) & (-2 \leq c \leq 0) \\
n/a & (|c| > 2).
\end{cases}
$$

The parameter $c$ tunes the Weyl point positions. The energy band spectrum is drawn in Fig. 3 with $p_3 = 0$ and $c = 1$. We see two Weyl points at $(p_1, p_2) = (\pm \pi/2, 0)$ at this section.

We introduce the boundary to this model. Suppose the lattice is defined on the region $n_3 \geq 1$, and impose the boundary condition

$$
(M + 1) \psi \bigg|_{n_3=1} = 0,
$$

where the matrix $M$ satisfies

$$
M^\dagger \sigma_3 + \sigma_3 M = 0.
$$

Then the situation is completely parallel with the continuum theory studied in the previous section. The matrix $M$ is parametrized by two parameters, $\theta_+$ and $\theta_-$, and the boundary condition is rephrased in terms of these parameters:

$$
\left( 1 - e^{-2i\theta_+} \right) \psi \bigg|_{n_3=1} = 0,
$$
which is equivalent to
\[ \psi_{n_3=1} \propto \begin{pmatrix} 1 \\ -e^{2i\theta_+} \end{pmatrix}. \]

Thus, it depends only on the parameter \( \theta_+ \) in the end.

We consider the spectrum and wave function behavior of the edge state under the boundary condition \((64)\). For the eigenvalue equation
\[ \mathcal{H}\psi = \epsilon(p)\psi, \]
the Hamiltonian has a matrix form in the partial Fourier basis,
\[ \mathcal{H} = \begin{pmatrix} 0 & \Delta(p)^\dagger \\ \Delta(p) & 0 \end{pmatrix} - i \frac{2}{\sigma_3} \left( \nabla_3 - \nabla_3^\dagger \right), \]
where the off-diagonal element is given by
\[ \Delta(p) = \cos p_1 - \cos p_2 + c + i \sin p_2, \]
which behaves as \( \Delta(p) \sim p_1 \pm ip_2 \) in the vicinity of the Weyl points. The sign \( \pm \) depends on the chirality of the Weyl points.

Assuming that the wavefunction is given by
\[ \psi_{n_3} = \beta^{n_3-1}\psi_1 \]
with the real parameter \( |\beta| \leq 1 \), the eigenvalue equation \((68)\) is equivalent to
\[ D\psi_{n_3} = 0, \]
where
\[ D = -i \frac{2}{\sigma_3} \begin{pmatrix} \beta^2 - 2i\epsilon(p)\beta - 1 & 2i\Delta(p)^\dagger \beta \\ -2i\Delta(p)\beta & \beta^2 + 2i\epsilon(p)\beta - 1 \end{pmatrix}. \]

To obtain a nontrivial solution to this zero mode equation we assign the condition \( \det D = 0 \), which yields
\[ \beta^2 = 1 + 2(|\Delta(p)|^2 - \epsilon(p)^2) \\
-2\sqrt{|(\Delta(p)|^2 - \epsilon(p)^2)(|\Delta(p)|^2 - \epsilon(p)^2 + 1)}. \]

There are two solutions for \( \beta \geq 0 \) and \( \beta \leq 0 \). We remark that these two possibilities correspond to the doublers at \( p_2 = 0 \) and \( \pi \) in the momentum space.

Then, together with the boundary condition \((67)\), the zero mode equation \((72)\) gives
\[ D \begin{pmatrix} 1 \\ -e^{2i\theta_+} \end{pmatrix} = 0. \]

Since \( \beta \in \mathbb{R} \), we obtain
\[ \epsilon(p) = -\cos 2\theta_+ \text{ Re } \Delta(p) - \sin 2\theta_+ \text{ Im } \Delta(p), \]
\[ \tilde{\alpha}(p) = \sin 2\theta_+ \text{ Re } \Delta(p) - \cos 2\theta_+ \text{ Im } \Delta(p). \]
which is rewritten as a matrix form
\[
\begin{pmatrix}
\epsilon(p) \\
\tilde{\alpha}(p)
\end{pmatrix} = -\begin{pmatrix}
\cos 2\theta_+ & \sin 2\theta_+ \\
-\sin 2\theta_+ & \cos 2\theta_+
\end{pmatrix} \begin{pmatrix}
\text{Re} \Delta(p) \\
\text{Im} \Delta(p)
\end{pmatrix},
\] (78)
where we define \(\tilde{\alpha}(p) := \frac{1}{2}(\beta^{-1} - \beta)\), and from Eq. (70), the real and imaginary parts of \(\Delta(p)\) are given by
\[
\text{Re} \Delta(p) = \cos p_1 - \cos p_2 + c, \\
\text{Im} \Delta(p) = \sin p_2.
\] (79) (80)

Comparing with the continuum theory (44), now the situation is parallel under the replacement
\[
(p_1, p_2, \alpha(p)) \rightarrow (\text{Re} \Delta(p), \text{Im} \Delta(p), \tilde{\alpha}(p)).
\] (81)

Figure 4 shows the boundary parameter dependence of the bulk and edge state dispersions. The edge state spectrum has a support only where the normalizability condition is satisfied, \(|\beta| \leq 1\). As mentioned before, there are two solutions corresponding to positive and negative \(\beta\). We focus on the positive solution in the following. When we change the parameter \(\theta_+\), the edge state spectrum rotates around the Weyl points. The orientation, that is, how the edge state spectrum winds, depends on the chirality of the Weyl nodes. This result is consistent with the continuum theory analysis, in particular in the vicinity of the Weyl points.

To see the parameter dependence more explicitly, let us take the constant energy section of the spectrum, which yields the Fermi arc shown in Figs. 5 and 6. This shows that the parameter characterizing the boundary condition \(\theta_+\) plays the role of the rotation angle of the Fermi arc, as studied in continuum theory. In the present case of the lattice models, the Fermi arc ends on the Weyl points and
Fig. 5. The parameter dependence of the Fermi arc that is the zero energy section $\epsilon(p) = 0$ of the edge state energy spectrum with $2\theta_+ = 0, 2\pi/5, 4\pi/5, 6\pi/5, 8\pi/5$ for positive $\beta$. The horizontal and vertical axes are for $p_1$ and $p_2$. The red dot shows the bulk Weyl node. The last panel shows Fermi arcs with various values of the parameter $\theta_+ \in [0, \pi)$.

has a finite support in the momentum space. Such a behavior of the Fermi arc has been experimentally observed, for example in the transition metal pnictide family [22].

Let us comment on the Fermi arc behavior corresponding to the negative $\beta$ solution. In this case the Fermi arc appears in the region $\tilde{\alpha}(p) < 0$, which is the complement to $\tilde{\alpha}(p) > 0$ for the positive $\beta$ solution. In addition, the rotation orientation for $\beta < 0$, depending on the boundary condition $\theta_+$, is the same as that for $\beta > 0$, as shown in Fig. 7, and thus the winding number is also the same for both cases. This implies that these two contributions from the positive and negative $\beta$ solutions are not canceled with each other.

3.3. Reduction to 2D class A system

As mentioned in Sect. 2.4 for continuum theory, the 3D Weyl semimetal system is translated to a 2D class A system using dimensional reduction. Let us try to apply this reduction to the systematic study on a lattice, and see how the topological edge state behaves under the generic boundary condition.
Fig. 6. The parameter dependence of the Fermi arc that is the finite energy slice \( \epsilon(p) = 0.3 \) of the edge state energy spectrum with \( 2\theta_+ = 0, 2\pi/5, 4\pi/5, 6\pi/5, 8\pi/5 \) for positive \( \beta \). The horizontal and vertical axes are for \( p_1 \) and \( p_2 \). The shaded region shows the bulk spectrum. The last panel shows Fermi arcs with various parameters \( \theta_+ \in [0, \pi) \).

Replacing the momentum \( p_1 \) or \( p_2 \) with the constant mass parameter \( m \) in the 3D Hamiltonian (62), we obtain the 2D class A system

\[
\mathcal{H}_1(p) = \sigma_1 (\cos m_1 - \cos p_2 + c) + \sigma_2 \sin p_2 + \sigma_3 \sin p_3, \\
\mathcal{H}_2(p) = \sigma_1 (\cos p_1 - \cos m_2 + c) + \sigma_2 \sin m_2 + \sigma_3 \sin p_3.
\]

(82) (83)

This is the dimensional reduction along the \( p_{1,2} \) direction. Putting the boundary at \( n_3 = 1 \), we can apply the same self-conjugacy argument to obtain the boundary condition as in the 3D system (66). Thus the edge state spectrum is given by

\[
\left( \begin{array}{c}
\epsilon \\
\alpha
\end{array} \right) = - \left( \begin{array}{cc}
\cos 2\theta_+ & \sin 2\theta_+ \\
-\sin 2\theta_+ & \cos 2\theta_+
\end{array} \right) \left( \begin{array}{c}
\text{Re} \Delta(p_{1,2} = m_{1,2}) \\
\text{Im} \Delta(p_{1,2} = m_{1,2})
\end{array} \right).
\]

(84)

Figures 8 and 9 show the bulk and edge state dispersions depending on the boundary condition parameter \( \theta_+ \), which is again consistent with the continuum theory. Such a dependence of the
Fig. 7. The Fermi arcs for positive $\beta$ (blue) and negative $\beta$ (orange) solutions at $2\theta_+ = 0$. The rotation orientation depending on the boundary condition $\theta_+$ is the same for both cases.

Fig. 8. The bulk and edge state dispersions from $p_1$-direction reduction with $c = 1$, $m_1 = \pi/2 + 0.5$, and the boundary condition parameter $\theta_+ = 2\pi/7, 4\pi/7, 6\pi/7, 8\pi/7, 10\pi/7, 12\pi/7$ for positive $\beta$. The horizontal and vertical axes are for $p_2$ and $\epsilon$. 
Fig. 9. The bulk and edge state dispersions from $p_2$-direction reduction with $\epsilon = 1, m_2 = 0.2$ and the boundary condition parameter $\theta_+ = 2\pi/7, 4\pi/7, 6\pi/7, 8\pi/7, 10\pi/7, 12\pi/7$ for positive $\beta$. The horizontal and vertical axes are for $p_1$ and $\epsilon$. The boundary condition was recently predicted to be observed in monolayer silicene/germanene/stanene nanoribbons [23].

4. The bulk–edge correspondence

In this section, we study the relation between the bulk and the edge states, and check the bulk–edge correspondence. We will see that for the most generic boundary conditions, the bulk–edge correspondence for the 2D topological phase works perfectly. The bulk–edge correspondence [5–7] for topological insulators is well known, while that for 3D Weyl semimetals has been understood in a way through a dimensional reduction to 2D. We claim here that the bulk–edge correspondence for the 3D Weyl semimetals can be defined as follows: the topological number of the bulk counts the chirality of the Weyl fermions, while the topological number of the edge is defined through the orientation of the Fermi arcs attached to the Weyl cone. This is based on our analysis on most general boundary conditions of the Weyl semimetals.

In the following, first we investigate the case of two dimensions, then later we discuss the case of three dimensions, the Weyl semimetals.
4.1. 2D topological phases with the most general boundary conditions

For the bulk–edge correspondence for the 2D topological insulator of class A, the formula is given by

$$k = n_+ - n_-,$$  \hspace{1cm} (85)

where $k$ is the bulk topological number (the TKNN number) and $n_\pm$ counts the number of right-/left-moving edge states.

In two dimensions, both sides of Eq. (85) should be understood as the difference under sign flip of the parameter $m$ for each cone. The topological number $k$ is defined as the difference in the TKNN number when $m$ changes its sign:

$$k = \nu(m > 0) - \nu(m < 0).$$  \hspace{1cm} (86)

As for the topological number of the gapless edge states, in our single-fermion problem, we choose it as the sign of

$$\frac{\partial \epsilon}{\partial p_1}.$$  \hspace{1cm} (87)

When it has a plus sign, we denote it as $n_+ = 1$, and when it has a minus sign, we denote it as $n_- = 1$.

Using these definitions, we check various cases with different values of $\theta_\pm$, and we find that all are consistent with the bulk–edge correspondence (85). Here, as an illustration, we show only two typical examples. In Fig. 10, when $2\theta_+ = \frac{3}{4}\pi$, we have

$$n_+(m > 0) = 1, \ n_-(m > 0) = 0;$$
$$n_+(m < 0) = 0, \ n_-(m > 0) = 0;$$

and when $2\theta_+ = \pi/4$, we have

$$n_+(m > 0) = 0, \ n_-(m > 0) = 0;$$
$$n_+(m < 0) = 0, \ n_-(m > 0) = 1.$$
Fig. 11. How to count the number of edge states from the orientation of the Fermi arcs. Left: a Fermi arc emanates from the Weyl node with a positive chirality $K = 1$, which is counterclockwise. Right: the case of the opposite chirality, $K = -1$.

Both cases have

$$\Delta n_+ - \Delta n_- = 1.$$  \hfill (88)

On the other hand, the TKNN number is calculated as

$$\nu(m > 0) = 1/2, \quad \nu(m < 0) = -1/2,$$

so we find consistency in these two examples:

$$k = \Delta n_+ - \Delta n_-.$$  \hfill (89)

In this way, for all possible values of $\theta_+$, we show the bulk–edge correspondence. This means that the correspondence is true for any consistent boundary conditions in two dimensions.

4.2. 3D Weyl semimetals with the most general boundary conditions

Let us turn to the case of three dimensions, the Weyl semimetals. In three dimensions, the topological number $K$ is defined by the wrapping number of a map $b_i(p_j)$, which shows up in the Hamiltonian

$$\mathcal{H} = b_i(p_j)\sigma_i.$$  \hfill (90)

Our Hamiltonian (1) is given by $b_i = p_i$, and the Weyl node is at $p_i = 0$. Considering a two-sphere surrounding the Weyl node, we obtain

$$K = 1 \in \pi_2(S^2).$$  \hfill (91)

We claim the bulk–edge correspondence for the 3D Weyl semimetal is given by

$$K = N - \tilde{N},$$  \hfill (92)

where $K$ is the topological number defined above. We define $N$ and $\tilde{N}$ to count the numbers of edge states with independent orientations with respect to the orientation of the bulk dispersion cone, as we will see below.

To discuss the orientation, we have to view the bulk dispersion in the subspace $(p_1, p_2)$, since the edge dispersion lives in that space. First, in the $(p_1, p_2, \epsilon)$ space, we notice that all constant $p_3$ slices of the bulk states have the same orientation. Let us make a further slice at a constant positive energy $\epsilon$. The cross section of the bulk dispersion is a circle (see Fig. 11). The orientation of the circle is definite due to the topological number (assuming $b_3 = p_3$).
The constant energy slice of the edge dispersions defines the Fermi arcs. Since generically the edge state dispersions are planes tangent to the bulk dispersions, the Fermi arcs share the same property. The number $N$ counts the number of Fermi arcs that are tangential to the bulk dispersion circle and emanate in a counterclockwise orientation. On the other hand, the number $\tilde{N}$ counts the number in a clockwise orientation.\footnote{Note that $N$ and $\tilde{N}$ defined here are meaningful only with their associated Weyl cone. For example, for an edge state connecting two Weyl cones, the numbers $N$ and $\tilde{N}$ cannot be defined in a uniform way.} Our claim for the bulk–edge correspondence is that this orientation of the bulk circle remains the same for the edge (the Fermi arcs).

Let us check this explicitly for two typical examples. In Fig. 11 we show the Hamiltonian (1) with $\theta_+ = 0$, and the case of the Hamiltonian $\mathcal{H} = -p_1 \sigma_1 + p_2 \sigma_2 + p_3 \sigma_3$ with $\theta_+ = 0$. The former case has $K = 1$, as explained before, while the latter case has $K = -1$. As we can see in Fig. 11, it is obvious that we have $(N, \tilde{N}) = (1, 0)$ for the former case, and $(N, \tilde{N}) = (0, 1)$ for the latter case. So, they are consistent with our claim of the bulk–edge correspondence (92).

All the edge states in Fig. 1 have the same $N$ and $\tilde{N}$ according to our definition: $(N, \tilde{N}) = (1, 0)$. So they are consistent again with Eq. (92). The examples in the lattice models we considered are shown to be consistent with the bulk–edge correspondence. Note that Fermi arcs join Weyl nodes, and our counting works for each Weyl node. To be more precise, each Fermi arc has two end points, and one end has $(N, \tilde{N}) = (1, 0)$ while the other end has $(N, \tilde{N}) = (0, 1)$. So the numbers are assigned to each end point of the Fermi arc.

### 5. New topological structure and Berry phase

In Sect. 2, we saw that the boundary condition of the 3D Weyl semimetals, as well as that of the 2D system, has only a single real parameter $\theta_+$. Since this $\theta_+$ is a new parameter describing the system with a boundary, we can think of it as a coordinate in the theory space. Normally, for a given Hamiltonian, the theory space is spanned by parameters of the Hamiltonian. From a topological viewpoint, the parameters are conserved momenta. The 3D Weyl semimetals are of that category, and the parameter dependence of the Hamiltonian defines the bulk topological charge. Now, once we introduce the boundary, one of the momenta becomes ill-defined and drops off the list of the parameters. However, a set of new parameters shows up describing the boundary condition. From the analyses of this paper, we know that the new parameter is only $\theta_+$. So, the most general parameter space of the 3D Weyl semimetals with a boundary in the continuum limit is described by $(p_1, p_2, \theta_+)$. 

To look for a novel topological structure of the system with a boundary, we study the wave function of the edge states, which depends only on the three parameters $(p_1, p_2, \theta_+)$. The nontrivial topological structure can often be detected by a Berry phase in the parameter space. We will find that, for the present case, the only nonvanishing Berry connection is that for $\theta_+$, and it provides us with a nontrivial Berry phase along a path in the parameter space.

Before getting to the details, we first note that the important part is just the phase of the wave function, to obtain a nonzero Berry connection. Suppose that the phase of the wave function does not depend on a parameter $\beta$. Then we find easily that

$$\psi^* \frac{d}{d\beta} \psi = |\psi|^T \frac{d}{d\beta} |\psi| = (\frac{d}{d\beta} |\psi|^T) |\psi|.$$ \hspace{1cm} (93)
Under this equality, the Berry connection associated with the parameter \( \beta \) is

\[
A_\beta = i \psi^\dag \frac{d}{d\beta} \psi
\]

\[
= i |\psi^\dag| d |\psi|
\]

\[
= i \left( \frac{d}{d\beta} (|\psi^\dag| |\psi|) - \left( \frac{d}{d\beta} |\psi^\dag| |\psi| \right) \right)
\]

\[
= 0 - A_\beta,
\]

which means the vanishing of the Berry connection, \( A_\beta = 0 \).

Now, if we look at our general edge wave function (48), the phase does not depend on \( p_1 \) and \( p_2 \). Therefore, we conclude

\[
A_{p_1} = A_{p_2} = 0 \quad (94)
\]

in our generic parameter space.

However, the phase of the wave function (48) depends on \( \theta_+ \), and we can calculate the Berry connection as

\[
A_{\theta_+} = i \int dx^3 \psi^\dag \frac{d}{d\theta_+} \psi
\]

\[
= i \int dx^3 \alpha e^{-2\alpha x^3} e^{2i\theta_+} \frac{d}{d\theta_+} e^{-2i\theta_+}
\]

\[
= 1. \quad (95)
\]

Note here that the Berry connection for the edge state, which has \( x^3 \) dependence, needs in its definition the integral over \( x^3 \) space so that the connection becomes Hermitian. So, we have a nontrivial Berry connection along the parameter \( \theta_+ \), which dictates the most general boundary condition of the 3D Weyl semimetals.

With the non-vanishing Berry connection at hand, let us study a possible topological charge. The range of the parameter \( \theta_+ \) is, as was analyzed earlier, the period \( 0 < \theta_+ \leq \pi \). The point \( \theta_+ = 0 \) is identical with the point \( \theta_+ = \pi \), so it describes a circle.\(^3\) We consider a path going around this circle once, with some dependence on \( p_1 \) and \( p_2 \). Let us calculate the Berry phase \( \phi_B \) along this path in the parameter space \( p_1, p_2 \) and \( \theta_+ \). Using Eq. (95), we obtain

\[
\phi_B = \int_{\theta_+: 0 \rightarrow \pi} \left[ A_{p_1} dp_1 + A_{p_2} dp_2 + A_{\theta_+} d\theta_+ \right]
\]

\[
= \pi. \quad (96)
\]

This means that the edge state has a new topological charge, and its value is \( 1/2 \).

In this calculation we considered a closed path in the \((p_1, p_2, \theta_+)\) space. Let us check whether the path exists or not. For the edge state to exist, we need to satisfy the normalizability condition \( \alpha > 0 \). This amounts to a nontrivial relation

\[
\alpha = p_1 \sin 2\theta_+ - p_2 \cos 2\theta_+ > 0. \quad (97)
\]

\(^3\) Note that we have chosen the phase of the wave function of the edge states (48) such that \( \psi(\theta_+ = 0) = \psi(\theta_+ = \pi) \).
In changing $\theta_+$ from 0 to $\pi$, it is necessary to choose a path in the $(p_1, p_2)$ space so that the above inequality is satisfied. An example of such a path is given by $(p_1, p_2) = c(\sin 2\theta_+ - \cos 2\theta_+)$ with a positive constant $c$.

One may expect that the 2D case should have a similar topological number. Unfortunately, this is not the case. Since $\alpha$ has to be positive, a constant $m$ gives a constraint on $\theta_+$:

$$\alpha = p_1 \sin 2\theta_+ - m \cos 2\theta_+ > 0.$$  (98)

This has no solution for $p_1$ for a given $m$ and all possible $\theta_+$. For example, for any positive $m$, at $\theta_+ = 0$ there is no $p_1$ satisfying the inequality. In the same manner, for any negative $m$, at $\theta_+ = \pi/2$ there is no $p_1$. So, the constancy of $m$ does not allow any path going from $\theta_+ = 0$ to $\theta_+ = \pi$.

If we consider a special case of $m = 0$, then we can find a path satisfying (98). An explicit example is $p_1 = c \sin 2\theta_+$ with a positive constant $c$.

We conclude that the edge states of the 3D Weyl semimetals acquire a new topological charge in the space of parameters of the boundary conditions. The 2D gapped case eliminates the topological charge, but 2D gapless systems can have the topological charge. The topological charge winds the space of $\theta_+$, the only parameter dictating the most generic boundary conditions.

6. Summary and discussion

In this paper, we have studied the most general boundary conditions of the 3D Weyl semimetals in the continuum limit around the Weyl point. The boundary conditions are shown to be dictated by a single real parameter $\theta_+$ that takes a value on a circle in the range $0 < 2\theta_+ \leq 2\pi$. The edge state wave functions and their dispersion relations are obtained, and we find that the dispersion plane as a function of the remaining conserved momenta $(p_1, p_2)$ terminates at the bulk dispersion cone, as a tangential plane to it. The parameter $\theta_+$ corresponds to the rotation angle of the edge dispersion plane relative to the bulk Weyl cone.

We built a lattice Hamiltonian with a parameter at the boundary of the 3D square lattice, which reproduces the $\theta_+$ dependence of the edge dispersion relations. Introduction of a boundary mass term at the edge of the lattice leads to various shapes of the Fermi arcs joining Weyl nodes with opposite chiralities.

Through a dimensional reduction, the system becomes a 2D topological insulator of class A. The bulk–edge correspondence is found to be consistent for all values of $\theta_+$, meaning that for any generic boundary condition the bulk–edge correspondence works. We propose how to count the number of edge modes of 3D Weyl semimetals so that it becomes consistent with the correspondence between the number of edge states and the bulk topological charges.

Furthermore, we discover a new topological number for the edge states of the 3D Weyl semimetals. The topological charge is associated with a Berry phase along the path parameterized by $\theta_+$, the new parameter dictating all the boundary conditions. In Ref. [24], the Berry phase with respect to the boundary condition is also discussed.

Various values of the new parameter $\theta_+$ can be realized in experiments. For example, a hydrogen termination of graphene and related materials has been studied [23], and the dispersion relations obtained from the microscopic lattice Hamiltonians exhibit a behavior that we have generically studied in this paper. To what extent our $\theta_+$ could be realized in experiments is one of the interesting future issues.

The meaning of the newly found topological charge needs to be verified in more detail. The topological charge owned by the edge modes was studied in Ref. [25] for 4D topological insulators,
inspired by a connection to superstring theory [26]. The edge topological charge would indicate the existence of edge-of-edge states. For the present case, the topological charge is obtained by the change in $\theta_+$, that is, the boundary condition itself. Therefore, to have such an edge-of-edge state, one needs to change $\theta_+$ as a function of the location on the boundary. It would be quite interesting if there exists such a topologically protected edge-of-edge state for 2D and 3D gapless systems.

In this paper our motivation came from a particle-theoretical viewpoint to explore all possible boundary conditions in the continuum limit of the Weyl semimetals. As we summarized above, our approach turned out to give fruitful results in condensed matter physics. Bridges between condensed matter physics and particle physics will play crucial roles in the coming advances in physics.

Appendix A. Momentum-dependent generic boundary condition

In this appendix, we study generic momentum-dependent boundary conditions. We shall prove that the two properties of the edge state dispersions described at the end of Sect. 2.3 are not modified even under a generic momentum dependence in the boundary conditions.

In the analysis so far, we have considered only a constant matrix $M$. This is because we are basically dealing with the small-momentum limit where the Weyl point is approximated by a relativistic dispersion relation. Since the bulk Hamiltonian is linear in the momenta, we could also allow a linear dependence for the boundary Lagrangian, which means $M$ linear in $p$. Since the boundary is at $x^3 = 0$, good quantum numbers are only $p_1$ and $p_2$, so in $M$ let us allow a linear dependence in $p_1$ and $p_2$. Since these are just parameters, the constraint equation for $M$ is obtained in the same manner, to have $A_1^2 + A_2^2 - B_3^2 = 1$. Although $A_1$, $A_2$, and $B_3$ are linear in $p_1$ and $p_2$, this constraint equation is quadratic. This means that the linear approximation of the boundary matrix $M$ breaks down. One needs higher-order terms in $p_1$ and $p_2$ to have a consistent boundary condition.

Let us formally continue the study of having a consistent momentum-dependent boundary condition and allow higher-order terms of the momenta in $M$. Since we have shown above that generic boundary condition is completely dictated by the parameter $\theta_+$, this means that $\theta_+$ will depend on the momenta, $\theta_+(p_1, p_2)$. Thus, we have a function–parameter family of the boundary condition, whose edge state has a dispersion

$$\epsilon = -p_1 \cos(2\theta_+(p_1, p_2)) - p_2 \sin(2\theta_+(p_1, p_2)).$$  \quad (A.1)

Let us show that this generalized boundary condition also shares the same properties as that for the constant $\theta_+$. First, let us check that the edge dispersion intersects with the bulk dispersion. The latter is a disk for a given energy $\epsilon$,

$$\epsilon^2 \geq p_1^2 + p_2^2.$$  \quad (A.2)

Supposing that the boundary of the disk shares a point with the edge dispersion, we denote it as

$$(p_1, p_2) = \epsilon (\cos a, \sin a).$$  \quad (A.3)
The existence of \( a \) means that the edge dispersion intersects with the bulk dispersion. Substituting this expression into the edge state dispersion (A.1), we find an equation for \( a \),

\[
\cos(a - 2\theta_+(\epsilon \cos a, \epsilon \sin a)) = -1.
\] (A.4)

This is equivalent to

\[
2\theta_+(\epsilon \cos a, \epsilon \sin a) = a + (2n + 1)\pi, \quad n \in \mathbb{Z}.
\] (A.5)

Since the left-hand side of this equation is a periodic function of \( a \), we can show that this equation always has an odd number of solutions for \( a \) in the period \( 0 \leq a < 2\pi \). Thus the edge dispersion always intersects with the bulk dispersion.

Next, let us show that the edge dispersion is always tangential to the Weyl cone. At the intersection point, we have a solution \( a = a_0 \) of Eq. (A.4). At \( a = a_0 \), the tangential line of the bulk dispersion at a constant \( \epsilon \) has a slope \( -\cot a_0 \) in the \((p_1, p_2)\) space, since the Weyl cone at a slice of constant \( \epsilon \) is just the disk. Let us show that the edge dispersion (A.1) also has the same slope at the intersection. Differentiating the dispersion relation (A.1) with respect to \( p_2 \), we find

\[
\frac{dp_1}{dp_2} = -\frac{\sin 2\theta_+}{\cos 2\theta_+} + \left(\frac{\sin 2\theta_+}{\cos 2\theta_+} p_1 - p_2\right) \frac{d(2\theta_+)}{dp_2}.
\] (A.6)

By using the intersection condition (A.4) and (A.3), we can simplify this equation to

\[
\frac{dp_2}{dp_1} = -\cot a_0,
\] (A.7)

which shows nothing but the slope \( -\cot a_0 \) in the \((p_1, p_2)\) space. This completes the proof that the edge dispersion is tangential to the bulk dispersion.

Finally, we show that the intersection point is in fact the point where the edge dispersion ends. To show it, we notice that the termination condition of the edge dispersion is \( \alpha = 0 \), since the existence of the edge is certified by \( \alpha > 0 \). Now, for the momentum-dependent \( \theta_+ \), we have the same formula

\[
\alpha = p_1 \sin (2\theta_+(p_1, p_2)) - p_2 \cos (2\theta_+(p_1, p_2)).
\] (A.8)

Substituting the intersection condition (A.3) and (A.4), we can show that

\[
\alpha \bigg|_{a=a_0} = 0.
\] (A.9)

This means that the edge dispersion is actually terminated at the intersection point, thus the edge is absorbed into the bulk.

In this manner, we can show that, even when a completely generic momentum dependence is allowed in the boundary condition, the edge dispersion keeps the properties that it is tangential to the bulk Weyl cone and it is terminated there.

**Appendix B. Two parallel boundaries**

In the main part of this paper, we study the general case of a single flat surface as a boundary. For realistic materials, two parallel boundaries are typical, and in this appendix we analyze the Weyl semimetal with two parallel boundaries, \( x^3 = 0 \) and \( x^3 = L \), in the continuum limit.
Each boundary can have the parameter $\theta_+$, so the number of parameters grows as one introduces many boundaries. In this subsection, just for simplicity, we consider the case with identical values of $\theta_+$ for the two boundaries.

Since the bulk Hamiltonian is not altered, the energy eigenvalue (35) does not change, thus a generic solution is

$$\begin{pmatrix} \xi \\ \eta \end{pmatrix} = e^{-\alpha x^3} \begin{pmatrix} \xi_1 \\ \eta_1 \end{pmatrix} + e^{\alpha x^3} \begin{pmatrix} \xi_2 \\ \eta_2 \end{pmatrix}, \quad (B.1)$$

with (37). Note here that we need to include another mode $\exp[\pm \alpha x^3]$ because the allowed region of $x^3$ is a finite period $0 \leq x^3 \leq L$.

Now, Eq. (35) leads to

$$\begin{pmatrix} i\alpha - \epsilon & p_1 - ip_2 \\ p_1 + ip_2 & -i\alpha - \epsilon \end{pmatrix} \begin{pmatrix} \xi_1 \\ \eta_1 \end{pmatrix} = 0, \quad (B.2)$$

$$\begin{pmatrix} -i\alpha - \epsilon & p_1 - ip_2 \\ p_1 + ip_2 & i\alpha - \epsilon \end{pmatrix} \begin{pmatrix} \xi_2 \\ \eta_2 \end{pmatrix} = 0. \quad (B.3)$$

On the other hand, the boundary condition at $x^3 = 0$ and $x^3 = L$ leads to

$$\begin{pmatrix} 1 & e^{-2i\theta_+} \\ e^{-2i\theta_+} & 1 \end{pmatrix} \begin{pmatrix} \xi_1 + \xi_2 \\ \eta_1 + \eta_2 \end{pmatrix} = 0, \quad (B.4)$$

$$\begin{pmatrix} 1 & e^{-2i\theta_+} \\ e^{-2i\theta_+} & 1 \end{pmatrix} \begin{pmatrix} e^{-\alpha L} \xi_1 + e^{\alpha L} \xi_2 \\ e^{-\alpha L} \eta_1 + e^{\alpha L} \eta_2 \end{pmatrix} = 0, \quad (B.5)$$

which are equivalent to

$$\begin{pmatrix} 1 & e^{-2i\theta_+} \\ e^{-2i\theta_+} & 1 \end{pmatrix} \begin{pmatrix} \xi_1 \\ \eta_1 \end{pmatrix} = (1 & e^{-2i\theta_+} \\ e^{-2i\theta_+} & 1 \end{pmatrix} \begin{pmatrix} \xi_2 \\ \eta_2 \end{pmatrix} = 0. \quad (B.6)$$

So, we can solve the wave function as if the two boundaries are just a set of copies of a single boundary, thanks to our assumption that the same boundary conditions are shared by the two. Together with Eqs. (B.2) and (B.3), we have the zero-mode equations

$$\begin{pmatrix} i\alpha - \epsilon & p_1 - ip_2 \\ 1 & e^{-2i\theta_+} \end{pmatrix} \begin{pmatrix} \xi_1 \\ \eta_1 \end{pmatrix} = 0, \quad (B.7)$$

$$\begin{pmatrix} -i\alpha - \epsilon & p_1 - ip_2 \\ 1 & e^{-2i\theta_+} \end{pmatrix} \begin{pmatrix} \xi_2 \\ \eta_2 \end{pmatrix} = 0. \quad (B.8)$$

If both of these have nontrivial eigenvector solutions, it leads to

$$(i\alpha - \epsilon)e^{-2i\theta_+} = (-i\alpha - \epsilon)e^{-2i\theta_+} = p_1 - ip_2. \quad (B.9)$$

However, this equation has no solution for generic $p_1$ and $p_2$. Therefore, either Eq. (B.7) or Eq. (B.8) is solved by a trivial vanishing solution.
When Eq. (B.7) has a nontrivial solution, $\xi_2 = \eta_2 = 0$, then the wave function and the energy eigenvalue are completely identical to the previous case of a single boundary:

$$\epsilon = -p_1 \cos 2\theta_+ - p_2 \sin 2\theta_+, \quad (B.10)$$
$$\alpha = p_1 \sin 2\theta_+ - p_2 \cos 2\theta_. \quad (B.11)$$

This is the edge state dispersion, which turns out to be identical to the single boundary case, (44).

On the other hand, when Eq. (B.8) has a nontrivial solution, then $\xi_1 = \eta_1 = 0$ and we obtain another edge state

$$\epsilon = -p_1 \cos 2\theta_+ - p_2 \sin 2\theta_+, \quad (B.12)$$
$$\alpha = -p_1 \sin 2\theta_+ + p_2 \cos 2\theta_. \quad (B.13)$$

This expression differs by just the sign of $\alpha$, compared to the previous one. Furthermore, since the front factor is $\exp[\alpha x^3]$, which differs only by the sign of $\alpha$ compared to the previous one, this solution turns out to be identical to the previous one. So, we conclude that we have a single edge state given by Eqs. (B.10) and (B.11).

The only difference compared to the single boundary case is that now there is no restriction $\alpha > 0$. In fact, depending on the momenta ($p_1, p_2$), $\alpha$ can be positive or negative, and this will affect whether the wave function localizes at $x^3 = 0$ or $x^3 = L$. Thus, the obtained edge state, although written in a unified form, represents both the modes, one localized at $x^3 = 0$ and the other at $x^3 = L$.
